ABSTRACT

We present the E-field Parallel Imaging Calibration (EPICal) algorithm, which addresses the need for a real-time calibration method for direct imaging radio astronomy correlators. Direct imaging involves a spatial fast Fourier transform of antenna **signals**, alleviating an $\mathcal{O}(N_a^2)$ **computational bottleneck typical in radio correlators**, and yielding a more gentle $\mathcal{O}(N_a \log_2 N_a)$ **scaling**. This can save orders of magnitude in computation cost for next generation arrays consisting of hundreds to thousands of antennas. However, because **antenna** signals are mixed in the correlator, gain correction must be applied **prior to imaging, rather than on visibilities post-correlation**. We develop the EPICal algorithm to form gain solutions in real time without ever forming visibilities. This method scales as the number of antennas, and produces results comparable to those from visibilities. **We use simulations to demonstrate the EPICal technique and study the noise properties of our gain solutions, showing they are similar to visibility based solutions in realistic situations. By applying EPICal to two seconds of Long Wavelength Array data we achieve a 65% dynamic range improvement compared to uncalibrated images, showing this algorithm is a promising solution for next generation instruments.**

Key words: instrumentation: interferometers – techniques: image processing – techniques: interferometric

1 INTRODUCTION

In order to satisfy the survey speeds required for precision cosmology as well as searches for fast radio transients, radio astronomy is undergoing a paradigm shift toward interferometers consisting of hundreds to thousands of small, widefield antennas. Many arrays with this design are already built or under construction including the Hydrogen Epoch of Reionization Array¹ (HERA), the Murchison Widefield Array (MWA; Tingay et al. 2013; Bowman et al. 2013), the Donald C. Backer Precision Array for Probing the Epoch of Reionization (PAPER; Parsons et al. 2010), the LOw Frequency ARray (LOFAR; van Haarlem et al. 2013), the Canadian Hydrogen Intensity Mapping Experiment (CHIME; Bandura et al. 2014), the Long Wavelength Array (LWA, Ellingson et al. 2013), and the low frequency Square Kilometer Array (SKA1- Low Mellema et al. 2013).

The most common radio correlator designs of today, the FX and lag correlators (Romney 1999), cross-multiply the **signals** from all pairs of **antennas**. This computation scales as the number of antennas squared, $\mathcal{O}(N_a^2)$ (Bunton 2004). As the number of elements in future arrays grows, the computational cost will become prohibitively expensive, and exploring efficient correlator schemes is essential to enable next generation instruments (Lonsdale et al. 2000). Meanwhile, radio transient monitoring requires access to high time and frequency resolution data to identify and characterize events such as fast radio bursts (FRBs, Lorimer et al. 2007), or to follow up gravitational wave candidates with radio observations (Abbott et al. 2016a; Abbott et al. 2016b). FRBs are highly unexplored at low frequencies (< 1 GHz), but are expected to occur on timescales $\Delta t \sim 1$ –10 ms (Thornton et al. 2013). Recording the full visibility matrix for $N_a \gtrsim 10^3$ arrays at this timescale leads to extremely high data rates.

Direct imaging correlators are a new variety of radio

correlator which aim to alleviate both the computational strain of forming N_a^2 correlations and the high data throughput associated with short timescale science. This is done by performing a spatial fast Fourier transform (FFT) to image the antenna signals, then squaring and averaging in time. This process scales as $\mathcal{O}(N_g \log_2 N_g)$, where N_g is the number of grid points in the FFT (Morales 2011; Tegmark & Zaldarriaga 2009; Tegmark & Zaldarriaga 2010). For certain classes of telescopes, significantly those envisioned for next generation cosmology experiments, this scaling is a large improvement over the N_a^2 scaling of traditional methods. Furthermore, because images are generated **in real-time**, the native output bandwidth will be lowered **in cases where** $N_g < N_a^2$, and has the potential to be lowered even further with **real-time** transient processing.

A handful of prototype direct imaging correlators have been tested on arrays including the Basic Element for SKA Training II (BEST-2) array (Foster et al. 2014), the Omniscope (Zheng et al. 2014), and an earlier pulsar timing experiment at GHz frequencies (Otoabe et al. 1994; Daishido et al. 2000). Each of these are examples of so-called FFT correlators – a subclass of direct imaging correlators which rely on identical antennas with restricted placement, which allows the FFT to be performed without gridding. We recently released the E-field Parallel Imaging Correlator (EPIC; Thyagarajan et al. 2015a), which is a software implementation of the Modular Optimal Frequency Fourier (MOFF; Morales 2011) imaging algorithm. This architecture leverages the software holography/A-transpose framework to grid electric field data streams before performing the spatial FFT, allowing for an optimal map without placing constraints on array layout or requiring identical antennas (Morales & Matejek 2009; Bhatnagar et al. 2008; Tegmark 1997b).

A challenge common to all direct imaging algorithms is calibration of the antenna gains. With a traditional **cross correlator**, visibilities are written to disk and used to calibrate **after observing and before further processing** such as imaging. However, a direct imaging correlator mixes the signals from all antennas before averaging and writing to disk, making calibration a requirement at the front end, before imaging and averaging. Previous solutions have involved applying calibration solutions generated from a parallel FX correlator (Zheng et al. 2014; Foster et al. 2014), or integrating a dedicated FX correlator which periodically formed the full visibility matrix to solve for gains (Wijnholds & van der Veen 2009; de Vos et al. 2009). While these solutions were sufficient to enable the exploration of FFT correlators and beamformers, they will not scale to future arrays with $N_a \gtrsim 10^3$.

Here we present the E-field Parallel Imaging Calibration (EPICal) algorithm – a novel solution to the calibration problem, which can be integrated into direct imaging correlators and scales only as the number of antennas, $\mathcal{O}(N_a)$. This method uses a correlation of the uncalibrated antenna signal stream with an output image pixel from the back-end of the correlator to solve for the complex gains of the antennas. Because the calibration must be applied before gridding and imaging, our solution requires an iterative approach where the data from one time series is used to update the gains which are applied to the following time series. An

Figure 1. Data flow for the MOFF algorithm, reproduced from Thyagarajan et al. 2015a. The time ordered electric field **measurements** are collected by the antenna elements then frequency transformed in the F-engine. The calibration is applied, then the electric field measurements are gridded using the **antenna aperture illumination patterns**. The imager performs a spatial 2D FFT on the gridded data before squaring and averaging. The accumulated images are then written to disk.

example implementation of the algorithm is available with the EPIC software package².

We review the MOFF algorithm and derive the calibration algorithm in §2. We then demonstrate the algorithm in simulations in §3, and discuss noise trends in §4. We then apply the algorithm to a sample LWA data set in §5. Finally we conclude and discuss potential extensions to the algorithm in §6.

2 MATHEMATICAL FRAMEWORK

2.1 Review of the MOFF algorithm

We begin by reviewing the data flow of the MOFF algorithm, highlighting aspects relevant to the calibration. The interested reader is encouraged to refer to Morales 2011 for a more thorough discussion. Figure 1 is reproduced from Thyagarajan et al. 2015a to illustrate the various steps of the algorithm.

We begin by considering the electric field vector incident on the ground as a function of time, $E(r, t)$. The position vector, r , is measured from some arbitrary origin. Following Clark 1999 we make a few assumptions in order to clarify notation and simplify the problem. First we note that the time ordered electric field can be expressed as a Fourier series with coefficients corresponding to frequencies f . This allows us to analyze the quasi-monochromatic components of the electric field, $E(r, f, t)$, with the understanding that the full field is composed of all components and their corresponding Fourier functions. We retain the time dependence because in

² <http://github.com/nithyanandan/EPIC>

practice each Fourier component will only be measured over discrete sampling intervals.

We will assume all antennas lie in a plane, reducing the problem to two dimensions. While the MOFF algorithm in principle can account for non-coplanar arrays through the W-projection algorithm (Cornwell et al. 2008), the EPIC code does not currently support this so we leave it to future work.

Next we treat the electric field as a scalar quantity, ignoring polarization effects. This allows us to express the electric field as a scalar, $E(\mathbf{r}, f, t)$, and treat subsequent field propagation and measurements as scalar rather than tensor multiplications. A full polarization treatment is required to construct polarized sky images, however the calibration will only require a sky model expressed in the instrumental polarization basis. We can therefore treat each instrument polarization independently.

Finally we assume the sources of the electric field are far away, allowing us to describe the electric fields propagating from sky sources as originating from an imaginary celestial sphere located a large distance from the ground. We express this intermediary electric field as an angular distribution, $\mathcal{E}(\hat{\mathbf{s}}, f, t)$, where $\hat{\mathbf{s}}$ is the unit vector in the direction of a patch of the celestial sphere. We further assume the space between the celestial sphere and the ground is empty, allowing us to express the electric field incident on the ground as a Fourier integral of the propagated fields across the hemisphere above the horizon.

$$E(\mathbf{r}, f, t) = \int \mathcal{E}(\hat{\mathbf{s}}, f, t) e^{-2\pi i f \mathbf{r} \cdot \hat{\mathbf{s}}/c} d\Omega \quad (1)$$

By making the latter assumptions we have left treatment of the ionosphere and terrestrial emission such as local interference or thermal radiation from the ground for future work.

Next we turn to the measurement performed by an antenna with frequency dependent far-field radiation pattern $\mathcal{W}_a(\hat{\mathbf{s}}, f)$, where the subscript a denotes a specific antenna. We adopt the common convention of normalizing the radiation pattern to have response of unity at the center of the main lobe (e.g. Napier 1999). Consequently, the translation between the terminal voltages to electric field measurements has been absorbed in our definition of the radiation pattern. The ideal antenna electric field measurement can be expressed as

$$E_a^I(f, t) = \int \mathcal{W}_a(\hat{\mathbf{s}}, f) \mathcal{E}(\hat{\mathbf{s}}, f, t) e^{-2\pi i f \mathbf{r} \cdot \hat{\mathbf{s}}/c} d\Omega. \quad (2)$$

Equivalently we can express the effect of the antenna radiation pattern in the plane of the aperture.

$$E_a^I(f, t) = \int_{\text{aperture}} \mathcal{W}_a(\mathbf{r} - \mathbf{r}_a, f) E(\mathbf{r}, f, t) d^2\mathbf{r} \quad (3)$$

Here we used the Fourier relationship between the antenna's far-field radiation pattern and the aperture illumination pattern (sometimes referred to as the aperture distribution),

$$\mathcal{W}_a(\mathbf{r} - \mathbf{r}_a, f) = \int \mathcal{W}_a(\hat{\mathbf{s}}, f) e^{-2\pi i f \mathbf{r} \cdot \hat{\mathbf{s}}/c} d\Omega. \quad (4)$$

While it is possible to define each antenna aperture illumination pattern in a way to absorb the relative position of the antenna, we keep the \mathbf{r}_a coordinate to retain the separable concepts of the primary beam (the product of two antenna radiation patterns) and the array point spread function (square of the Fourier transform of the array layout).

The first step of the MOFF algorithm is to digitize the antenna signals and perform an FFT to channelize the time-ordered data. This is effectively estimating the quasi-monochromatic components of the electric field. The bandwidth of the observation and the time sampling rate are related by $B = 1/\Delta t$, and the channelized frequency resolution and sampling period have the relation $\Delta f = 1/T$, according to the Nyquist theorem. The frequency Fourier transform operation is often referred to as the F-engine of a correlator. The MOFF shares the same F-engine design as an FX cross correlator which performs the frequency transform (F-engine) before cross multiplying (X-engine).

Thus far we have considered the perfectly measured electric field distribution according to the antenna far-field radiation patterns. Here we introduce a multiplicative complex gain as well as an additive noise term which corrupt the measured signals at each of the antennas.

$$E_a(f, t) = g_a(f, t) E_a^I(f, t) + n_a(f, t) \quad (5)$$

We have carried the frequency dependence to this point to make clear the complex gains are frequency dependent. However, each subsequent step treats each frequency channel independently, so we will drop the f to simplify notation. Furthermore, while antenna gains may vary with time, we will assume they are constant over the period of our calibration, and thus drop their time dependence from the notation.

The MOFF algorithm next calls for a calibration of the electric field measurements. The goal of our new calibration method will be to form an estimate of the gains, g'_a , where the prime represents an estimate. For now we will assume we have formed an estimate to proceed with the MOFF pipeline. We correct the incoming electric field data stream using our current estimate of the gains.

$$E'_a(t) = E_a(t)/g'_a \quad (6)$$

The next step is to grid the calibrated electric field measurements to a finite set of regularly spaced positions on the plane of the ground, \mathbf{r}_j . The extent of the grid is chosen to encompass the footprint of the antenna array. MOFF uses the antenna aperture illumination patterns as the gridding kernel according to the software holography/A-transpose technique (Morales & Matejek 2009; Bhatnagar et al. 2008). Mathematically we can express the gridding operation as

$$E'_j = \sum_a \mathcal{W}_a(\mathbf{r}_j - \mathbf{r}_a) E'_a(t) \quad (7)$$

Formally the value at each pixel is calculated by summing the antenna measurements over all antennas, each weighted by its respective aperture illumination pattern. However the aperture illumination

patterns are typically compact and non-overlapping, so most pixels will only contain contribution from one antenna, allowing equation 7 to be calculated through a sparse matrix multiplication. This gridding achieves an optimal map (Tegmark 1997a) and places the data on a regular grid. Unlike traditional correlators which grid visibilities, the MOFF grids the electric field measurements directly. This operation must be performed for every time sample, before any averaging of the data.

After gridding, the imaging portion of the MOFF performs a 2D spatial FFT to form instantaneous electric field images of the sky at fixed locations \hat{s}_k . The FFT is possible because we have gridded to regularly spaced samples in a 2D plane. The Fourier dual coordinates to \mathbf{r}_f/c are (l, m) , where $l = \sin \theta \cos \phi$, $m = \sin \theta \sin \phi$, and (θ, ϕ) are the zenith and azimuthal angles. The full unit vector towards the sky is $\hat{s} = (l, m, \sqrt{1 - l^2 - m^2})$. Being direction cosines, grid locations with $l^2 + m^2 > 1$ are non-physical and should be ignored.

The algorithm up to this point can be summarized through the following equation.

$$\mathcal{E}'(\hat{s}_k, t) = \underbrace{\frac{1}{N_a} \sum_j e^{2\pi i f \mathbf{r}_j \cdot \hat{s}_k / c}}_{\text{2D FFT}} \underbrace{\sum_a W_a(\mathbf{r}_j - \mathbf{r}_a)}_{\text{Gridding}} \times \underbrace{\frac{1}{g'_a} (g_a E_a^I(t) + n_a(t))}_{\text{Calibration}} \quad (8)$$

The sum over antennas uses the **antenna aperture illumination pattern** to grid the calibrated electric field measurements onto regular gridpoints, \mathbf{r}_j . The sum over j denotes the 2D FFT to sky coordinates, resulting in an estimate for the instantaneous electric field image. The sums over a and j mix the antenna signals together, which is the primary reason calibration must be performed beforehand where individual antennas retain their identities.

We can simplify the above expression by exchanging the sums and use the DFT to approximate the Fourier relationship between the antenna aperture illumination pattern and the far-field radiation pattern.

$$\begin{aligned} \mathcal{E}'(\hat{s}_k, t) &= \frac{1}{N_a} \sum_a \frac{1}{g'_a} (g_a E_a^I(t) + n_a(t)) e^{2\pi i f \hat{s}_k \cdot \mathbf{r}_a / c} \\ &\quad \times \sum_j W_a(\mathbf{r}_j - \mathbf{r}_a) e^{2\pi i f \hat{s}_k \cdot (\mathbf{r}_j - \mathbf{r}_a) / c} \\ &\approx \frac{1}{N_a} \sum_a \frac{1}{g'_a} (g_a E_a^I(t) + n_a(t)) e^{2\pi i f \hat{s}_k \cdot \mathbf{r}_a / c} \mathcal{W}_a(\hat{s}_k) \end{aligned} \quad (9)$$

In this form we see that the effect of gridding with the antenna aperture illumination pattern is to attenuate the image by a factor of the far-field radiation response, $\mathcal{W}_a(\hat{s})$. This added factor of the instrument response is sometimes referred to as the *holographic frame* in the literature (e.g. Morales & Matejek 2009; Sullivan et al. 2012).

Finally, the images are squared and averaged in time to form **dirty images**, $I'(\hat{s}_k)$, then written to disk. While operations have been reordered, the resulting image is equivalent to one produced by gridding and imaging visibilities.

By shifting from cross-correlation of all pairs of antennas to a spatial FFT, the computational cost is significantly lowered for certain classes of compact arrays. The output bandwidth is also greatly reduced in many scenarios as visibilities are replaced with gridded images. These scalings were explored in Thyagarajan et al. 2015a.

2.2 Derivation of calibration

We saw above that the MOFF algorithm (in general any direct imaging architecture) mixes the signal from all antennas coherently, and thus requires the calibration to be applied in real time **before imaging**. Furthermore, visibilities are never formed, which are traditionally the basic measurement used to form calibration solutions. Here we derive an alternative method to estimate the antenna gains in real time, using the data products of the MOFF.

Because the gains must be estimated in real time, we will need to use a finite stream of data to form an estimate which will be applied to the subsequent stream of data. We assume that the changes in gains are negligible over adjacent intervals, which in some cases may limit the length of data streams. Because data from one interval is used to update the gain solutions for the next, the process of finding a solution is an iterative one. We will use parenthetical superscripts to denote the calibration loop number. For example, we will assume we have already formed an estimate from n loops, $g_a^{(n)}$. We will use these estimates to calibrate the next stream of data in order to form an updated estimate, $g_a^{(n+1)}$.

As a starting point, we consider the feedback calibration outlined in Morales 2011. There it was suggested to form a correlation of the uncalibrated antenna measurements with the **complex conjugate** of an image pixel from the output of the correlator. This is a statistically stationary quantity, which can be related to the sum of visibilities involving the antenna used in the correlation – exactly the sum needed to calibrate in the case of a single point source sky. However, we aim for a more generalized solution for arbitrarily complex sky models. We therefore study the full expression for the antenna-pixel correlation,

$$\mathcal{K}_{a, \hat{s}_0}^{(n)} \equiv \langle E_a(t) \mathcal{E}'^*(\hat{s}_0, t) \rangle_{t^{(n)}}, \quad (10)$$

where the superscript n again represents the quantity formed in the n^{th} calibration loop, and we use $t^{(n)}$ outside the brackets on the right-hand side to indicate all quantities within the brackets are drawn from time samples in the n^{th} calibration loop. The superscript $*$ indicates complex conjugation, and \hat{s}_0 is the pixel center nearest a bright calibrator of interest. The following will hold for any chosen pixel, \hat{s}_0 , though it is advantageous to choose a pixel which contains a bright source to achieve a high signal to noise ratio.

Plugging equation 9 into equation 10, and substituting the $g_b^{(n)}$ for g'_b to indicate the specific loop num-

ber, we find,

$$\begin{aligned}
 \mathcal{K}_{a,\hat{s}_0}^{(n)} &= \left\langle \left(g_a E_a^I(t) + n_a(t) \right) \frac{1}{N_a} \right. \\
 &\quad \times \sum_b \frac{1}{g_b^{*(n)}} \left(g_b^* E_b^{I*}(t) + n_b^*(t) \right) \\
 &\quad \times e^{-2\pi i f \hat{s}_0 \cdot \mathbf{r}_b / c} \mathcal{W}_b^*(\hat{s}_0) \Big\rangle_{t^{(n)}} \\
 &= \frac{1}{N_a} \sum_b \frac{1}{g_b^{*(n)}} \mathcal{W}_b^*(\hat{s}_0) e^{-2\pi i f \hat{s}_0 \cdot \mathbf{r}_b / c} \\
 &\quad \times \left\langle \left(g_a E_a^I(t) + n_a(t) \right) \left(g_b^* E_b^{I*}(t) + n_b^*(t) \right) \right\rangle_{t^{(n)}} \\
 &= \frac{1}{N_a} \sum_b \frac{1}{g_b^{*(n)}} \mathcal{W}_b^*(\hat{s}_0) e^{-2\pi i f \hat{s}_0 \cdot \mathbf{r}_b / c} \\
 &\quad \times \left(g_a g_b^* \left\langle E_a^I(t) E_b^{I*}(t) \right\rangle_{t^{(n)}} + g_a \left\langle E_a^I(t) n_b^*(t) \right\rangle_{t^{(n)}} \right. \\
 &\quad \left. + g_b^* \left\langle n_a(t) E_b^{I*}(t) \right\rangle_{t^{(n)}} + \left\langle n_a(t) n_b^*(t) \right\rangle_{t^{(n)}} \right) \quad (11)
 \end{aligned}$$

where in the second step we group time-dependent terms, and in the third step we expanded the product within the time average. Because the noise does not correlate with the ideal antenna measurements we can drop the middle terms. We will also assume that the cross-correlation noise ($a \neq b$) is zero mean. Then by defining an ideal visibility as $V_{ab}^I \equiv \langle E_a^I(t) E_b^{I*}(t) \rangle_t$, we can simplify to

$$\begin{aligned}
 \mathcal{K}_{a,\hat{s}_0}^{(n)} &= \frac{1}{N_a} \sum_b \frac{1}{g_b^{*(n)}} \mathcal{W}_b^*(\hat{s}_0) e^{-2\pi i f \hat{s}_0 \cdot \mathbf{r}_b / c} \\
 &\quad \times \left(g_a g_b^* V_{ab}^I + \delta_{ab} \langle |n_a(t)|^2 \rangle_{t^{(n)}} \right) \quad (12)
 \end{aligned}$$

where δ_{ab} is the Kronecker-delta function. To be clear, visibilities are never directly formed from the data. Rather it is convenient to express $\mathcal{K}_{a,\hat{s}_0}^{(n)}$ in terms of the ideal visibilities, which we can model when solving for the gains below.

We will ultimately wish to model the right side of equation 12 in order to solve for the antenna gains. However, the self-correlated noise, $\langle |n_a(t)|^2 \rangle$, can often be significantly larger than the cross correlation power, and difficult to model precisely. It is therefore beneficial to subtract the self-correlation directly from $\mathcal{K}_{a,\hat{s}_0}^{(n)}$. By properly accounting for the various weighting and phasing terms, we can use self-correlations of the uncalibrated antenna electric field measurements to remove the corresponding terms from equation 12:

$$\begin{aligned}
 \mathcal{C}_{a,\hat{s}_0}^{(n)} &\equiv \mathcal{K}_{a,\hat{s}_0}^{(n)} - \frac{1}{N_a g_a^{*(n)}} \mathcal{W}_a^*(\hat{s}_0) e^{-2\pi i f \hat{s}_0 \cdot \mathbf{r}_a / c} \langle |E_a|^2 \rangle_{t^{(n)}} \\
 &= \frac{g_a}{N_a} \sum_{b \neq a} \frac{g_b^*}{g_b^{*(n)}} \mathcal{W}_b^*(\hat{s}_0) e^{-2\pi i f \hat{s}_0 \cdot \mathbf{r}_b / c} V_{ab}^I. \quad (13)
 \end{aligned}$$

Due to the above subtraction, the sum is now over $b \neq a$, explicitly removing the dependence on the self-correlated antenna signals.

The next step is to use this antenna-pixel correlation to update our gain solution. We will model the right hand side of equation 13 by assuming our current gain estimates are approximately correct, $g_b^{(n)} \approx g_b$, and replacing the ideal visibilities with a set of model visibilities, V_{ab}^M . These model visibilities rely on knowledge of the sky, and should be

Figure 2. The general data flow of the MOFF correlator, with a feedback calibration loop. A pixel from the (unsquared) image is tapped out and correlated against the input antenna electric field **measurements** to form $\mathcal{C}_{a,\hat{s}_0}^{(n)}$ coefficients (equation 13). These coefficients are then **used to update the gain estimates using** equations 14 and 15, and **any additional fitting** (Section 6). The gray box shows operations which must be done at high speed (before averaging in time), **while** the white boxes show operations which can be performed **at lower speeds because they involve time averaged quantities, and need to be updated on slower timescales.**

precomputed **before observing**. We can then solve equation 13 for g_a to achieve an updated estimate.

$$g_a^{(n+1)} = \frac{\mathcal{C}_{a,\hat{s}_0}^{(n)} N_a}{\sum_{b \neq a} \mathcal{W}_b^*(\hat{s}_0) e^{-2\pi i f \hat{s}_0 \cdot \mathbf{r}_b / c} V_{ab}^M} \quad (14)$$

This equation is our prescription for estimating the antenna gains of a direct imaging array. The **real-time** computation complexity scales as $\mathcal{O}(N_a)$ as we form an **antenna-pixel correlation**, $\mathcal{C}_{a,\hat{s}_0}^{(n)}$, for each antenna.

We show schematically the process of calibrating a direct imaging correlator in Fig. 2. Computationally expensive steps that must be performed in **near real-time** are shown inside the gray box. The uncalibrated antenna signals are tapped out after the F-engine and correlated against the output image pixel of interest (i.e., equation 13 is **computed in near real-time**). The correlated values are then **used to estimate the gains** using equation 14, and additional fitting if desired (see Section 6). **This step does not have the stringent cadence requirement of the steps in the gray box because the antenna-pixel correlations have been averaged in time.** The gains are then passed back to the correlator to update the calibration for subsequent integration intervals.

While testing we found equation 14 resulted in oscillatory gain solutions **over time**, as is often the case in iterative methods. To mitigate this we introduce a damping factor, $0 \leq \gamma < 1$, which is used to attenuate the gain update, effectively giving the solutions memory of previous iterations.

$$g_a^{(n+1)} = \frac{(1 - \gamma) \mathcal{C}_{a,\hat{s}_0}^{(n)} N_a}{\sum_{b \neq a} \mathcal{W}_b^*(\hat{s}_0) e^{-2\pi i f \hat{s}_0 \cdot \mathbf{r}_b / c} V_{ab}^M} + \gamma g_a^{(n)} \quad (15)$$

We found that while equation 14 does indeed converge on good solutions, the process is made faster by tuning the damping factor. Once the loop converges the damped version is essentially a weighted average over the past several iterations, giving **the solutions** a longer effective integration time.

We conclude this section by connecting our calibration expression to that found in a visibility framework. In the

limit of a single bright calibrating source **at zenith**, we can greatly simplify equations 13 and 14. We will assume the **radiation patterns** are normalized such that $\mathcal{W}(0) = 1$. We can further drop the exponential phase terms because $\hat{\mathbf{s}}_0$ is **perpendicular to our planar antenna array**. We then absorb the true gains into the true visibilities in equation 13 to express as a sum of measured, uncalibrated, visibilities.

$$\mathcal{C}_{a,0}^{(n)} \rightarrow \frac{1}{N_a} \sum_{b \neq a} \frac{1}{g_b^{*(n)}} V_{ab} \quad (16)$$

We next plug this expression into equation 14 to find our simplified calibration solution for a single bright point source. Because our sky is a single bright point source, the model visibilities are simply the flux of the source, S_{src} .

$$g_a^{(n+1)} \rightarrow \frac{\sum_{b \neq a} V_{ab}/g_b^{*(n)}}{N_a S_{\text{src}}} \quad (17)$$

This is simply a gain-weighted sum of the measured visibilities over the flux of the source, which is indeed the limiting result from a visibility approach, for example seen in Mitchell et al. 2008. The ability to recover the equivalent expression despite not actually forming the visibilities is a result of the fact that only sums over visibilities come into the **visibility-based** solution, as was described in Morales 2011. We have confirmed the limiting case equivalence here, and will explore the more general case in more detail in the following sections.

3 SIMULATION

We first demonstrate our calibration method through a controlled simulation. A complex gain is created for each antenna with random phase and amplitude, which is used to corrupt the simulated data stream, then we attempt to **estimate** the gains using our calibration routine. The simulation software used is included in the EPIC package.

Our simulated antenna array consists of the inner 51 antennas of the MWA layout (Beardsley et al. 2012), within a bounding box of 150 m. **The physical parameters of our simulation can be arbitrarily scaled to other cases. However, we provide typical units for an MWA observation as an example. The antenna aperture illumination pattern used is a 4.4 m square tophat; a very rough approximation to the square shaped tiles of the MWA.** Because our algorithm treats frequency channels independently, we simulate only one channel. For context we treat this as **a channel at 150 MHz with 40 kHz bandwidth, and adopt a sampling period of 25 μ s.** The simulated signal consists of 10 random point sources with flux densities $0.5 \text{ Jy} \lesssim S \lesssim 1 \text{ Jy}$ within the main lobe of the primary beam.

For our unknown gains, we create a set of random complex numbers where the amplitude is drawn from a **gaussian distribution centered around unity with width 0.25, and truncated at zero.** The gain phases are drawn from a uniform distribution in the range $[-\pi, \pi)$. These are our “true gains”, and we apply them to the frequency domain simulated antenna electric field **measurements** as in equation 5. Our analysis is blind to these values until the end of the process to check accuracy. The gain estimates are initialized with unity, $g_a^{(0)} = 1$.

Figure 3. Phase error of gain estimates as a function of iteration for simulated calibration. The gains were initialized with random phases, but the calibration loop was able to recover the correct phases after about 12 iterations. Each line represents an antenna in our 51 MWA antenna sample.

We next process and image 400 time **samples** (10 ms). We also form the **antenna-pixel** correlations, $\mathcal{C}_{a,\hat{\mathbf{s}}_0}^{(0)}$, used in our calibration loop. The pixel used for the correlation is the source with the largest apparent flux (intrinsic flux attenuated by the primary beam). These correlation values are used to update the gain estimates. **We create perfect model visibilities of our 10 simulated sources to be used in equation 15. The updated gain estimates are used to calibrate the following 400 time samples.** Through **trial and error** we found a damping factor of $\gamma = 0.35$ resulted in the quickest convergence in this simulation.

The calibration loop continues by updating the gain estimates every 400 time **samples**. The **phase errors** of our gain estimates are shown in Fig. 3 for 20 such iterations. The phase error plotted is the phase relative to the true gain for each antenna (various colored lines). One antenna was used as a reference to fix the absolute phase, so has zero phase error. The other 50 antennas are shown to have error spanning the range $[-\pi, \pi)$ initially, and after about 10 iterations lock into a solution, settling down to noise levels around iteration 12 (**0.12 s**). We stop the simulation when the updated gains trace the thermal noise of the simulated sources, which can be seen by the coherence of the 50 antenna gains after iteration 12.

The estimated gain amplitudes for the simulations are shown in Fig. 4. The quantity plotted is the magnitude of the estimated gains over the true gains, $|g_a^{(n)}/g_a|$, which places all antennas on the same scale. We can see the amplitudes converge toward their true values around the same time as the phases (iteration ~ 12). At the beginning of calibration we can see the **importance** of the damping factor. At $n = 0$, a couple of gains are shown to have abnormally high amplitude estimates, notably one about 3.3 times its true value (red line). These unbalanced high estimates caused the entire set of gains to be under estimated at $n = 1$, even with a damping factor of 0.35. By $n = 5$ the unbalanced ampli-

Figure 4. Same as Fig. 3, but for gain amplitudes. Each line represents an antenna in the 51 MWA antenna sample. The relative amplitude plotted is the magnitude of the estimated gains divided by the true gains. After about 12 iterations we see the calibration loop has settled around the correct values, with only noise remaining.

tudes have been damped out and the calibration continues. Without the damping factor, the oscillation seen in the first couple iterations would have been significantly larger and taken much longer to fade out.

After the gains have converged, we see both the phases and amplitudes continue to fluctuate coherently. This is due to the stochastic fluctuations of the sources themselves, **which are simulated as zero mean random processes with variance proportional to their flux density.** For this simulation we restricted each calibration iteration to only 10 ms integration time. In principle a calibration implementation could use short integration times to allow the gains to converge, then increase the integration time to reduce this noise.

Images created at the beginning of calibration and at the end are shown in Fig. 5. Each image is obtained over a 400 time sample (10 ms) integration, corresponding to all snapshot images created with a given set of gain estimates. The **left** panel shows the image produced with our initialized unity gains. Because the phases are completely random, the image is essentially noise with the primary beam evident. After 20 calibration iterations, the image is far more clear, shown in the **middle** panel. **The ten sources are visible, along with rumble throughout the image.** By comparing with a perfectly calibrated image (**right** panel), we see that the rumble and the shapes of the point sources are matched between the two images. We therefore conclude that the artifacts visible are dominated by the point spread function, rather than calibration errors.

4 NOISE TRENDS

Next we study the effect of noise in our system, and the consequences of an incomplete sky model. We run a suite

of simulations varying the receiver noise and integration times, while forming antenna-pixel correlations, $\mathcal{C}_{a,s_0}^{(n)}$, for EPICal gain solutions, and simultaneously forming visibilities from the same streams of **measured electric fields** to find visibility-based gain solutions for comparison.

We use a simulated sky consisting of a 5 Jy calibrator source, and 49 other random sources with apparent flux densities 0.2 to 0.5 Jy (total sky power ≈ 23 Jy). We generated these sources randomly, but kept them fixed for each run. **We simulate the same antenna layout as in Section 3. However, we increase the number of frequency channels simulated to 64, while keeping the flux of all sources constant across frequency.** Because our calibration loop treats frequency channels independently, each channel can be treated as a separate trial of the simulation, and is used to better estimate the statistics.

To simulate receiver noise, we add a gaussian distributed complex random number to each antenna electric field measurement at each time **sample** according to equation 5. The level of the receiver noise, $\sigma_r = \langle |n_a(f, t)|^2 \rangle$, is varied in different simulation runs. We include two limiting cases, **one** where the receiver noise power is subdominant to the sky power ($\sigma_r = 10.0$ Jy), and **the other** where the receiver **noise** dominates the total power ($\sigma_r = 100.0$ Jy).

For each simulation run we find gain solutions using four methods:

- i. EPICal, using a full sky model
- ii. EPICal, using a single point source model
- iii. Visibility-based, using a full sky model
- iv. Visibility-based, using a single point source model.

In the cases where we use the full sky model, the model visibilities, V_{ab}^M , used in the calibration loop are created using all point sources in the simulated sky. For the single point source model, we only **include the bright calibrator source in the model visibilities.** While we vary the model used for calibration, the simulated “true sky” remains fixed with all 50 point sources.

For EPICal, we initialize our gain estimates with the true values ($g_a^{(0)} = g_a = 1$), and allow the estimate to be corrupted by the noise through ten iterations of the calibration loop. **This allows us to bypass the initial convergence time and quickly study the effect of the noise over many simulations.** We again adopt a damping factor $\gamma = 0.35$. Because EPICal updates the gain estimate at each calibration loop, t_{cal} , but retains a memory of previous iterations through the damping factor, the total integration time is not straightforward. We define an effective integration time by considering the relative weights of each previous $\mathcal{C}_{a,s_0}^{(n)}$ contributing to the current $g_a^{(n)}$ estimate, each with integration time t_{cal} . In the limit $n \rightarrow \infty$, the geometric series converges to an effective integration time of

$$t_{\text{eff}} = t_{\text{cal}} \times \frac{1 + \gamma}{1 - \gamma}. \quad (18)$$

With the damping factor we adopted here, $t_{\text{eff}} \approx 2.1 \times t_{\text{cal}}$.

We simultaneously form simulated visibilities, V_{ab} , by correlating all pairs of antenna **electric field measurements** (including the receiver noise). The **electric field measurements are correlated** for a duration equal to the effective integration time of the EPICal loop for comparison. We then find the visibility-based gain estimates by

Figure 5. Images formed during simulated calibration. *Left:* An image generated from a single frequency channel and **400 time sample (10 ms)** integration after the gain estimates are randomized. As expected with random phases, the image is completely noisy, with the shape of the primary beam evident. *Middle:* An image formed after calibration, again with a single frequency channel and **400 time sample** integration. Now the simulated point sources are visible in the image. *Right:* An image generated from the same simulated data as the middle image, but with perfect calibration correction. Many of the features seen in the middle image are also seen here, confirming that they are point spread function artifacts. The ten simulated (and modeled) point sources are highlighted with red circles.

minimizing

$$\chi^2 = \sum_a \sum_{b \neq a} \left| V_{ab} - g_a g_b^* V_{ab}^M \right|^2, \quad (19)$$

using both versions of the model visibilities described above.

For each version of calibration, we observe the error in the gain estimates by averaging over both antennas and frequency channels.

$$\sigma_g = \left[\frac{1}{N_f N_a} \sum_f \sum_a \frac{|g_a^{(n)}(f) - g_a(f)|^2}{|g_a(f)|^2} \right]^{1/2} \quad (20)$$

The results of our simulations for all four calibration methods are shown in Fig. 6. In the case of the full sky model, we see the errors trend downward with longer integration times, as expected. The EPICal errors are slightly higher than the visibility-based errors, on average about 23% difference. This is not surprising as EPICal only uses the information in a single pixel, while the visibilities use all information from the full sky model. However, we see that with this perfect model the errors do behave like noise in the sense that they integrate down with longer integrations with the expected $t^{-1/2}$ trend. With longer integration time (or larger damping factor), EPICal can achieve the same level of gain error as visibility based solutions.

The exact ratio of noise in gains from EPICal and the visibility-based estimator depends on the fraction of the total sky power contained in our calibrator source. In the example here, our calibrator accounted for 22% of the total sky power. We repeated the experiment in the regime where the calibrator dominated the sky and found that the difference in EPICal and visibility-based error goes to zero, as expected. For a typical HERA observation, the sky temperature is expected to be about 180 K (Jacobs et al. 2015), and a bright calibrator source could be about 10% of this power. In this regime we found that EPICal gain noise was

Figure 6. Gain estimate errors as a function of integration time, receiver noise (line color), and calibration method. The solid lines represent the error on the EPICal derived gain estimates, while the dashed lines represent the error on the visibility based estimates. The thicker lines were derived using a full sky model in the calibration loops, and the thinner lines used only a single point source model. In the full sky model case we see all methods trend down with longer integration time as expected. For a given integration time, EPICal derived errors are on average 23% higher than those of visibility based calibration. In the case of a single source model, the errors bottom out due to the flux in the measurements that is not modeled. In this regime the EPICal method performs slightly better than the visibility-based method due to effectively beamforming to the sky pixel where the incomplete model is most accurate. On average EPICal errors are 5% lower in this regime. **The results from the high and low receiver noise regimes are similar, with both approaching the same floor in the single source model case.**

about 60% higher than visibility-based gain noise for the same effective integration time.

In a more realistic situation, the observer will not have a perfectly complete model of the sky. A common method is to instead model the brightest sources in the field, or even a single dominant source. When using the single point source model, all calibration methods in Fig. 6 trend downward until they reach an error floor due to the confusion sources that were not modeled. The EPICal and visibility-based solutions reach a similar floor, but EPICal achieves a marginally lower level (on average 5% lower). This can be attributed to the same reason EPICal underperformed with the full sky model: EPICal only used a single pixel in the sky to form its solutions. When using the full sky model, it was **under utilizing** the information in the rest of the sky. But when the sky model only contains the bright point source, the single pixel used in EPICal is the location where this model is most accurate, effectively down weighting the pixels with incomplete sky model. **In contrast, the visibility-based calibration method does not have any preference to a certain direction, and weights the sky equally (beyond the inherent response of the instrument). This results in a more harsh penalty for missing sources in the model.** In the regime typical of HERA discussed above, EPICal’s error floor was 10% lower than that of visibility-based solutions.

Any realistic sky model will lie somewhere between the two extremes explored here. In the case where the sky is modeled by a single source, as is often the case for an initial calibration, EPICal actually achieves smaller gain errors compared to the traditional visibility-based calibration. As the sky model improves, both visibility-based and EPICal gains improve, though the former quicker than the latter. In the limit of a perfect model, both calibration methods produce noise-like errors in their gains which scale down with more integration time.

Comparing the two regimes of receiver noise levels (red versus black lines in Fig. 6), we see that the gains errors behave as one might expect given our above interpretations. In the case of a perfect sky model, the higher receiver noise results in larger gain errors for a given integration time, but follows the same $t^{-1/2}$ noise trend. The imperfect model lines begin exhibit the same offset at low integration time because the errors are dominated by the thermal noise. But as integration time increases, they approach the same floor due to the same level of power from unmodeled sources.

5 APPLICATION TO LWA DATA

We next demonstrate our calibration algorithm using an observation from the LWA station in New Mexico (Ellingson et al. 2013). The data is from the LWA narrow-band transient buffer (TBN), with time ordered voltage data from the 255 core antennas within a **110 m x 100 m ellipse**. The central frequency is 74.03 MHz, with a bandwidth of 100 kHz and **sampling period** of 5.12 ms (frequency channel resolution of 195.3125 Hz). For this demonstration we limit ourselves to a single polarization.

After correcting for geometric cable delays, the instrument is naturally well calibrated, as was seen in the demonstration of the EPIC imager in Thyagarajan et al. 2015a. However, we will aim to further improve on this calibration using our algorithm.

We proceed by forming model visibilities. We model only two bright objects as point sources: Cyg A with flux **20,539 Jy**, and Cas A with flux **19,328 Jy** (Lane et al. 2012). Because the raw data is attenuated by the primary beam of the instrument, we also account for this in our model using beam values consistent with Hicks et al. (2012).

We made several choices while studying the behavior of the LWA data to improve our calibration. Through our previous imaging work, we noted that the flux scale of uncalibrated images was consistent with average gain amplitudes of roughly 0.25. To allow the calibration to converge quickly we initialized our gain estimates at this level. We also found a boost in signal to noise is achieved easily by **assuming the gains are constant across a range of frequencies, and averaging solutions across channels**. Here we average solutions across **300 channels**, or about **58.6 kHz**. With a fractional bandwidth $B/f_0 = 7.9 \times 10^{-4} \ll 1$, we assume a smooth bandpass across the band. A damping factor of $\gamma = 0.7$ was adopted. **The large damping factor, relative to what was used in simulations, was necessary due to the larger noise levels in the LWA data compared to the ideal simulations. This yields a larger effective integration time, and thus lower noise on each calibration solution (Eq. 18)**

Finally, we found that seven antennas³ produced unstable gain solutions, and in fact corrupted the entire array. We therefore **omitted these antennas from our analysis**, resulting in a total of 248 antennas to calibrate. In each calibration loop, we form $C_{i,\hat{s}_0}, i = 1, 2, \dots N_a$ and update our gain estimates over **10 samples** (51.2 ms). We iterate the loop 30 times for a total of 1.536 seconds of data processed. The results of this calibration experiment are shown in Figs. 7 – 9.

Figure 7 shows the phase of our gain estimates over 30 calibration iterations, again with each colored line representing a different antenna. Given the quality of uncalibrated image demonstrated in Thyagarajan et al. (2015a), we had anticipated that the phase solutions would not exhibit much variation between antennas. Hence the relatively large variation was unexpected. However, the phases are relatively flat after about 15 iterations (modulo noise), and exhibit a central “trunk” where the majority of phases are congregated. This behavior is suggestive that while the uncalibrated data were able to produce a viable image, the minor changes from our solutions will focus the image and improve the quality. The actual location of the “trunk” (slightly negative) is simply determined by the reference antenna chosen to have identically zero phase, but happens to be slightly more positive than the bulk of antennas.

The gain amplitudes as a function of calibration iteration are shown in Fig. 8. There is a fairly wide range in gain amplitudes (from 0.12 to 0.59). However, this is not

³ LWA antenna IDs 48, 85, 124, 148, 203, 217, and 244 were omitted.

Figure 7. Gain phase solutions as a function of calibration iteration for an LWA TBN observation. The gain estimates are initialized with zero phase, but quickly span a 2π range, and settle into relatively flat, albeit noisy, solutions. The majority of phases congregate near zero, which is not surprising given the fairly good quality image produced from uncalibrated data. **For plotting clarity, we unwrapped phases resulting in phases that appear to exceed $\pm\pi$.**

surprising due to the non-uniformity in the cables from the antennas to the receivers. Again, the amplitudes are noisy but relatively flat.

To ensure the level of noise in our solutions is reasonable we compared to the fractional errors from our simulations shown in Fig. 6. We first use the Global Sky Model (de Oliveira-Costa et al. 2008) to generate a mock observed sky at 74.03 MHz using the PyGSM python module⁴ (Price 2016). We integrate this model to estimate a total sky flux power of 171,000 Jy, meaning our calibration pixel containing Cyg A accounts for approximately $20,539/171,000 \approx 12\%$ of the total sky power. This places us in a regime similar to the incomplete sky model simulations of the previous section, where the calibration pixel accounted for 21.7% of the sky power. We should therefore expect our fractional gain noise levels to be at best around 0.1, the level to which the simulations asymptotically approached.

To estimate the fractional gain noise of our solutions we calculate the standard deviation of the gain estimates after iteration 15 for each antenna separately. We then divide these standard deviations by the respective mean gain amplitudes. This resulted in a distribution of fractional gain noise centered at 0.15 and a width of 0.04 ($\approx 0.15/\sqrt{15}$). This noise level is consistent with what we expected from the simulations. There were four outliers with noise levels significantly outside the distribution ($\sigma_g \approx 0.29$). Upon closer inspection the gain amplitudes of these

Figure 8. Same as Fig. 7, but for gain amplitudes. The gains estimates were initialized with amplitude 0.25 after inspection of the electric field values compared to our model sky. The solutions are noisy, but flat. The range in amplitudes is due to the non-uniformity of cables between the LWA antennas and receivers.

outliers had converged later in the calibration loop, after iteration 15.

Figure 9 shows the improvement in the images due to our calibration. The left panel shows the uncalibrated image integrated over 51.2 ms, 58.6 kHz. Cyg A is prominent near the center of the image, and Cas A is also clearly visible in the upper right. The middle panel shows the image produced after calibration with identical integration time and bandwidth. We show each of these images with a color scale which saturates at half the maximum value in the respective image data. We find that this choice allows us to qualitatively compare the quality of the images, independent of the absolute scale which changed during the calibration. The sidelobes throughout the calibrated image are significantly suppressed, and the galactic plane is much more evident, despite only modeling Cyg A and Cas A. We also note that the feature just to the right of Cyg A is dimmer in the calibrated image, better matching the expected flux from the GSM. For reference we show the GSM in the right panel of Fig. 9, convolved by the LWA point spread function and weighted by two factors of the primary beam to match the holographic frame of the data images.

To compare the image qualities quantitatively we compute the dynamic range, defined as the peak of the image over the noise level. We estimate the noise level as the median of the absolute deviation of the image. With this metric we find the uncalibrated and calibrated images to have dynamic ranges of 80.4 and 133.1, respectively, a 65% improvement.

6 DISCUSSION

Through simulations and application to real data, we have shown that the EPIC algorithm is a viable solution for cal-

⁴ <https://github.com/telegraphic/PyGSM>

Figure 9. Images produced before (left) and after (middle) calibrating LWA data. These images were produced with **58.6 kHz** bandwidth and 51.2 ms integration. **The color scales are saturated at half the peak of the respective images.** The calibrated image shows significant reduction in **rumble** throughout, while retaining the prominent Cyg A and Cas A sources. The galactic plane is also substantially more evident after calibration. For reference, the GSM is shown in the right panel convolved with the LWA point spread function and weighted by two factors of the primary beam to place it in the same holographic frame as the data images. While much of the GSM is visible in the calibrated image, we note that the model used to calibrate was only the two bright sources, Cyg A and Cas A.

ibrating direct imaging arrays in real time. The computation necessary only scales with the number of antenna elements, making it a sub-dominant cost factor when designing the correlator. This strategy will enable fast read-out for arrays with many thousands of antennas, which will be necessary for future radio transient and cosmology experiments.

EPICal can be further improved through several extensions. Here we name a few potential considerations for further study. These topics can be thought of as extensions to the white “estimate gains” box in Fig. 2, which can be performed at a much **slower rate** than the actual antenna-pixel correlations.

Multiple pixel correlations. As was seen in section 4, the single pixel correlation demonstrated in this paper can underperform in the presence of a complex sky, when compared to visibility-based gains with perfect knowledge of the sky. These errors can be mitigated by using correlations of multiple image pixels to incorporate a higher fraction of the total sky power into the calibration loop. Of course this increases the computational cost to a scaling of $\mathcal{O}(N_a N_{\text{pix}})$, which will typically be much lower than the $\mathcal{O}(N_g \log_2 N_g)$ of the correlator itself. These additional correlations would also enable direction dependent gain solutions. Each correlation could be used to independently solve for gains in each pixel direction, then fit to a beam model on the sky. This updated beam pattern would then feed into the gridding step of the correlator, allowing the imager to convolve the signals with the effective beam pattern in the ground plane.

Fitting gain models. With some knowledge of the instrumental bandpass, the noise of the gain solutions can be greatly reduced by fitting a model to the per-frequency solutions derived here. We used this method at a rudimentary level in our demonstration to LWA data by assuming the gains were constant over a narrow bandwidth. One could easily improve on this by extending the bandwidth and fitting for a low order polynomial in phase and amplitude. Additionally, with knowledge of **any filters applied to the**

data stream in the receiver chain, we could include channels closer to the edge of the band.

Improving sky model. In this work we used a perfect sky model (for simulation), or a very simple sky model (for LWA data). In principle the images produced by the EPIC correlator can be used to improve the sky model used in calibration – similar to a major loop in self-calibration. This can be especially useful for compact, widefield arrays which require a model of both compact and diffuse sources over a large patch of sky. **As with any sky-based calibration scheme, EPICal requires that the sky model be attenuated by the primary beam**, which can be difficult to measure at the precision necessary (e.g. Neben et al. 2015; Virone et al. 2014; Thyagarajan et al. 2015b). However, the direct imaging correlator provides exactly the **product of the sky and beam** necessary, and can be iterated over to improve the images and gain solutions, **leaving final beam correction to post-processing as in traditional processing.**

Dynamic parameters. In our controlled experiments we fine-tuned a number of parameters based on our testing (e.g. damping factor, integration time, frequency averaging). A deployed system will require robust determination of these parameters to operate continuously. The specifics will be heavily dependent on the stability of the instrument, the frequency of observation, and the sky. For example, a stable instrument may be able to use short integrations to determine a rough estimate of the gains before switching to much longer integration (on order seconds to minutes) to highly increase signal to noise. At low frequencies or high imaging resolution, the dynamics of the ionosphere are important, and will likely drive the limit of time integration allowed.

The work here will serve as a foundation for further development. We have shown that the EPICal algorithm produces reliable calibration solutions, and have identified several aspects to increase the scope. With next generation

instruments in the planning and development stages, EPICaI is poised to **enable new design spaces**. The software is integrated into the EPIC package and freely available to use in simulations or **post-processing** of data. Work is underway to port the code to real-time GPU systems for deployment.

ACKNOWLEDGEMENTS

This work has been supported by the National Science Foundation through award AST-1206552. We thank Danny Jacobs for his valuable inputs, and Greg Taylor for providing us with LWA data. Construction of the LWA has been supported by the Office of Naval Research under Contract N00014-07-C-0147. Support for operations and continuing development of the LWA1 is provided by the National Science Foundation under grant AST-1139974 of the University Radio Observatory program.
