ABSTRACT

Abstract here (250 words)

Key words: instrumentation: interferometers – techniques: image processing – techniques: interferometric

1 INTRODUCTION

Radio astronomy is entering an era in which interferometers of hundreds to thousands of individual antennas are needed to achieve desired survey speeds. Nowhere is this more apparent than at radio frequencies below 1.4 GHz. The study of the history of hydrogen gas throughout the universe’s evolution is pushing technology development towards arrays of low-cost antennas with large fields of view and densely packed apertures. Similarly, the search for transient objects and regular monitoring of the time-dependent sky is driving instruments in the same direction. A number of new telescopes are under development around the world based on this new paradigm, including the Murchison Widefield Array (MWA, [Tingay et al. 2013](#)), the Precision Array for Probing the Epoch of Reionization (PAPER, [Parsons et al. 2010](#)), the Hydrogen Epoch of Reionization Array (HERA ¹), the Low Frequency ARray (LOFAR, [de Vos et al. 2009](#)), the Canadian Hydrogen Intensity Mapping Experiment (CHIME, [Bandura et al. 2014](#)), the Long Wavelength Array (LWA, [Ellingson et al. 2013](#)), and the low frequency component of the Square Kilometer Array Low Frequency Aperture Array (SKA-Low [Mellema et al. 2013](#)).

This paradigm shift requires a fundamentally new approach to the design of digital correlators ([Lonsdale et al. 2000](#)). Modern correlators calculate the cross-power correlation between all antenna pairs in many narrow frequencies, forming *visibilities*, the traditional fundamental measurement of radio interferometers. The computational requirements for a modern FX correlator scale with the number of antenna pairs, or the square of the number of antennas $\sim N_{\text{ant}}^2$ ([Bunton 2004](#)). For this reason traditional correlators have difficulty scaling to thousands of antennas. As an example, the full HERA correlator for 352 dishes with 200 MHz of bandwidth requires 212 trillion complex multiplies and adds per second (TMACS). Future arrays with thousands of collecting elements will

require orders of magnitude more computation, making the correlator the dominant cost.

For certain classes of radio arrays there is an alternative to the FX correlator that can lower the computational burden by directly performing a spatial fast Fourier transform (FFT) on the electric fields measured by each antenna in the array at each time step, removing the cross-correlation step. This relieves the computational scaling from the harsh N_{ant}^2 to the more gentle envelope of $N_{\text{pix}} \log N_{\text{pix}}$, where N_{pix} is the number of pixels in the Fourier transform (e.g. [Morales 2011](#); [Tegmark & Zaldarriaga 2009](#); [Tegmark & Zaldarriaga 2010](#)). This architecture is often referred to as a “direct imaging” correlator because it eliminates the intermediary cross-correlation data products of the FX and earlier lag correlators, but instead directly forms images from the electric field measurements.

Direct imaging correlators have begun to be explored on deployed arrays including the Basic Element for SKA Training II (BEST-2) array ([Foster et al. 2014](#)), the Omniscope ([Zheng et al. 2014](#)), and an earlier incarnation at higher frequencies with the intent of pulsar timing ([Otoabe et al. 1994](#); [Daishido et al. 2000](#)). However, each of these examples make assumptions about the redundancy of the array layout, and require the collecting elements are identical. On the other hand, the MOFF algorithm achieves the same $N_{\text{pix}} \log N_{\text{pix}}$ computational scaling without placing any restriction on antenna placement, can accommodate non-identical beam patterns, and is a provably optimal mapping ([Morales 2011](#)). This algorithm uses the antenna beam patterns to grid the electric field measurements to a regular grid in the software holography/A-transpose fashion ([Morales & Matejek 2009](#); [Bhatnagar, S. et al. 2008](#); [Tegmark 1997a](#)) before performing the spatial FFT. This process has been shown to theoretically produce a data product identical to images produced from the traditional FX correlator.

Here we present the first software implementation of the MOFF correlator, and announce the public release of the E-field Parallel Imaging Correlator (EPIC) code. We begin with a technical description of the algorithm in §2, then discuss our particular implementa-

¹ <http://reionization.org>

tion in §3. We then verify the output data quality from our code in §4 by presenting simulated images from both the EPIC correlator and comparing to a simulated FX correlator. We also demonstrate the performance with real-world data from the LWA. In §5 we analyze the scaling relationships of the algorithm. We identify specific array design classes where the EPIC correlator is computationally more efficient than the FX algorithm. We conclude and discuss future research prospects in §6.

2 MATHEMATICAL FRAMEWORK

We provide a brief summary of the mathematical equivalence of the MOFF and FX correlators detailed in Morales (2011). We first relate the dirty image produced from visibilities to the electric fields of astrophysical sources, then show that operations can be reordered to produce the same images at a lower computational cost.

Electric fields from astrophysical sources, $E(\hat{s})$, in the sky coordinate system denoted by sine-projected unit vector \hat{s} , propagate towards the observer as:

$$\tilde{E}(\mathbf{r}) = \int E(\hat{s}) e^{-i2\pi\mathbf{r}\cdot\hat{s}} d^2\hat{s}, \quad (1)$$

where, \mathbf{r} denotes the observer's location (measured in wavelengths relative to some arbitrary origin) and $\tilde{E}(\mathbf{r})$ is the propagated electric field. Thus the propagated electric field is a linear superposition of the electric fields emanating from astronomical sources with appropriate complex phases. It can also be described as a Fourier transform of the electric fields in the sky coordinates.

An antenna, a , measures a phased sum of these propagated electric fields over its effective collecting area with an additive receiver noise:

$$\tilde{E}_a = \int \tilde{W}_a(\mathbf{r} - \mathbf{r}_a) \tilde{E}(\mathbf{r}) d^2\mathbf{r} + \tilde{n}_a \quad (2)$$

$$= \int \tilde{W}_a(\mathbf{r} - \mathbf{r}_a) \left[\int E(\hat{s}) e^{-i2\pi\mathbf{r}\cdot\hat{s}} d^2\hat{s} \right] d^2\mathbf{r} + \tilde{n}_a \quad (3)$$

$$= \int W_a(\hat{s}) E(\hat{s}) e^{-i2\pi\mathbf{r}_a\cdot\hat{s}} d^2\hat{s} + \tilde{n}_a \quad (4)$$

where, $\tilde{W}_a(\mathbf{r})$ is the aperture electric field illumination pattern of the antenna and its Fourier transform, $W_a(\hat{s})$, is the directional antenna voltage response.

Interferometers measure *visibilities* – the degree of coherence between electric fields measured by a pair of antennas (van Cittert 1934; Zernike 1938; Thompson et al. 2001). A visibility, \tilde{V}_p , can be written as:

$$\tilde{V}_p = \langle \tilde{E}_a \tilde{E}_b^* \rangle_t \quad (5)$$

$$= \left\langle \left[\int W_a(\hat{s}) E(\hat{s}) e^{-i2\pi\mathbf{r}_a\cdot\hat{s}} d^2\hat{s} + \tilde{n}_a \right] \times \left[\int W_b^*(\hat{s}') E^*(\hat{s}') e^{i2\pi\mathbf{r}_b\cdot\hat{s}'} d^2\hat{s}' + \tilde{n}_b^* \right] \right\rangle_t \quad (6)$$

$$= \iint W_a(\hat{s}) W_b^*(\hat{s}') \langle E(\hat{s}) E^*(\hat{s}') \rangle_t e^{-i2\pi(\mathbf{r}_a\cdot\hat{s} - \mathbf{r}_b\cdot\hat{s}')} d^2\hat{s} d^2\hat{s}', \quad (7)$$

where we have brought the time average into the integral under the assumption that the aperture illumination pattern does not change over the time-scale of the averaging. This expression can be further simplified with the sky brightness, $I(\hat{s}) = \langle E(\hat{s}) E^*(\hat{s}') \rangle_t \delta(\hat{s} - \hat{s}')$, and defining the antenna pair sky power response function (or the primary beam), $B_p(\hat{s}) \equiv W_a(\hat{s}) W_b^*(\hat{s})$. The result is the visibility

expressed in terms of the sky brightness, the primary beam, and uncorrelated noise terms which we group into \tilde{n}_p ,

$$\tilde{V}_p = \int e^{-i2\pi\mathbf{u}_p\cdot\hat{s}} B_p(\hat{s}) I(\hat{s}) d^2\hat{s} + \tilde{n}_p, \quad (8)$$

where the baseline coordinate $\mathbf{u}_p = \mathbf{r}_a - \mathbf{r}_b$ is the vector separation between the two antennas. This signifies that the visibility (\tilde{V}_p) measured between a pair of antennas (p) is obtained by the multiplying the sky brightness $I(\hat{s})$ by the antenna power response $B(\hat{s})$ and Fourier transforming from the directional coordinates (\hat{s}) to uv coordinates, which are then sampled at the locations of the antenna spacings (or baselines), namely, \mathbf{u}_p , and added to the receiver noise n_p .

This can be equivalently re-written as:

$$\tilde{V}_p = \int \tilde{B}(\mathbf{u}' - \mathbf{u}) \times \left[\int e^{-i2\pi\mathbf{u}\cdot\hat{s}} I(\hat{s}) d^2\hat{s} \right] d^2\mathbf{u} + n_p, \quad (9)$$

where, $\tilde{B}(\mathbf{u})$ denotes the uv -space antenna power response obtained by a Fourier transform of $B(\hat{s})$. Effectively, the multiplication in image space by $B(\hat{s})$ has been replaced by a convolution with $\tilde{B}(\mathbf{u})$ in uv -space. This is the software holographic equivalent of traditional FX correlator output.

From here we adopt the matrix notation of Morales (2011), where vectors are represented with single coordinates, and matrices are represented by two coordinates denoting the spaces the operator transforms between. In this notation, the above measurement equation can be expressed as:

$$\mathbf{m}(\mathbf{v}) = \tilde{\mathbf{B}}(\mathbf{v}, \mathbf{u}) \mathbf{F}(\mathbf{u}, \hat{s}) \mathbf{I}(\hat{s}) + \mathbf{n}(\mathbf{v}), \quad (10)$$

where the sky brightness $\mathbf{I}(\hat{s})$ is Fourier transformed using $\mathbf{F}(\mathbf{u}, \hat{s})$ and the resultant spatial coherence function is weighted and summed using the antenna power response, $\tilde{\mathbf{B}}(\mathbf{v}, \mathbf{u})$ in uv -space sampled at the baseline location to obtain the measured visibilities:

$$\mathbf{m}(\mathbf{v}) = \langle \tilde{\mathbf{E}}^*(\mathbf{a}) \tilde{\mathbf{E}}(\mathbf{a}') \rangle_t, \quad (11)$$

where $\mathbf{m}(\mathbf{v})$ denotes visibilities measured by cross-correlating measured antenna electric fields over all possible pairs of \mathbf{a} and \mathbf{a}' . It is the same as equation 5 written in matrix notation.

Using the optimal map-making formalism (Tegmark 1997b; Tegmark 1997a), a software holography image is formed using (Morales & Matejek 2009):

$$\mathbf{I}'(\hat{s}) = \mathbf{F}^T(\hat{s}, \mathbf{u}) \tilde{\mathbf{B}}^T(\mathbf{u}, \mathbf{v}) \mathbf{N}^{-1}(\mathbf{v}, \mathbf{v}) \mathbf{m}(\mathbf{v}) \quad (12)$$

where the measured visibilities are weighted by the inverse of the system noise, followed by a gridding process using the holographic antenna power response as the gridding kernel, followed by a Fourier transform to create an image $\mathbf{I}'(\hat{s})$. This is the optimal estimate of the true image $\mathbf{I}(\hat{s})$ given the visibility measurements.

The intermediate step of gridding with the antenna power response can be expressed as a convolution of a data vector generated by gridding the electric fields directly with the antenna illumination pattern.

$$\begin{aligned} \tilde{\mathbf{B}}^T(\mathbf{u}, \mathbf{v}) \mathbf{N}^{-1}(\mathbf{v}, \mathbf{v}) \mathbf{m}(\mathbf{v}) = \\ \left\langle \left[\tilde{\mathbf{W}}_a^T(\mathbf{r}, \mathbf{a}) \tilde{\mathbf{N}}^{-1}(\mathbf{a}, \mathbf{a}) \tilde{\mathbf{E}}(\mathbf{a}) \right] * \left[\tilde{\mathbf{W}}_a(\mathbf{r}, \mathbf{a}) \mathbf{N}^{-1}(\mathbf{a}, \mathbf{a}) \mathbf{E}^*(\mathbf{a}) \right] \right\rangle_t \end{aligned} \quad (13)$$

We can then use the multiplication-convolution theorem to move the convolution in Equation 13 to a square after the Fourier transform in Equation 12.

$$\mathbf{I}'(\hat{s}) = \left\langle \left| \mathbf{F}^T(\hat{s}, \mathbf{r}) \tilde{\mathbf{W}}^T(\mathbf{r}, \mathbf{a}) \tilde{\mathbf{N}}^{-1}(\mathbf{a}, \mathbf{a}) \tilde{\mathbf{E}}(\mathbf{a}) \right|^2 \right\rangle_t. \quad (14)$$

The term inside the angular brackets before squaring has a very similar form as that in equation 12. It signifies that the measured antenna electric fields are weighted by the antenna noise, weighted and gridded by the antenna aperture kernel, Fourier transformed and finally squared to obtain the same image estimated that would have been obtained using equation 12.

Equation 14 is the optimal imaging equation used by the MOFF algorithm. While mathematically equivalent to Equation 12, squaring in image space rather than convolving in uv space potentially saves orders of magnitude in computation.

There are some important differences between the two techniques:

(i) The time-averaging cannot be performed on a stochastic measurement but only on its statistical properties. In FX imaging, the visibilities measured between antenna pairs represent spatial correlations which can be time-averaged followed by gridding and imaging. However, in MOFF imaging both antenna and gridded electric fields are stochastic and therefore must be imaged and squared before time-averaging.

(ii) In FX imaging, electric fields measured by antennas are not correlated with themselves and hence lack zero spacing measurements. In contrast, in MOFF imaging, since the gridded electric fields are imaged and squared, they contain information from auto-correlated electric fields at zero spacing. Hence, they must be subtracted from the images.

3 SOFTWARE IMPLEMENTATION

We have implemented the MOFF imaging technique in our “E-field Parallel Imaging Correlator” – a highly parallelized Object Oriented Python package,² now publicly available. Besides implementing the MOFF imaging algorithm it also includes FX imaging using the software holography technique and a simulator for generating electric fields from a sky model.

Fig. 1 shows the flowchart for MOFF imaging. The propagated electric fields are shown on the left at different time stamps, $t_1 \dots t_M$. At each time stamp, the electric fields measured by antennas are denoted by $E_1(t) \dots E_N(t)$. The F-engine performs a temporal Fourier transform on the electric field time-series to obtain electric field spectra $E_1(f) \dots E_N(f)$ ($\vec{E}(\mathbf{a})$ in matrix notation) for each of the antennas. Each of the complex antenna gains are calibrated to correct the corresponding electric field spectra. These calibrated electric fields are gridded using an antenna-based gridding convolution function after which it is spatially Fourier transformed and squared to obtain images for every time stamp. These images are then time-averaged to obtain the accumulated image $I(f)$ ($\mathbf{I}(\hat{s})$ in matrix notation).

Fig. 2 shows the flowchart for software holographic imaging from a FX correlator. The antenna-based F-engine is identical to that in the MOFF processing. The electric field spectra from each antenna are then cross-multiplied in the X-engine with those from all other antennas to obtain the visibilities $V_{ij}(f)$ ($\mathbf{m}(\mathbf{v})$ in matrix notation). They are calibrated and time-averaged to obtain $\langle V_{ij}(f) \rangle$ which are then gridded and imaged to obtain the image $I(f)$. The $I(f)$ obtained from both techniques are identical as explained in §2.

Here, we discuss the components of these architectures in detail.

Figure 1. A flowchart of MOFF imaging in EPIC. The propagated electric fields shown on the left are measured as time-series $E_1(t) \dots E_N(t)$ by the antennas which are then Fourier transformed by the F-engine to produce electric field spectra $E_1(f) \dots E_N(f)$. They are calibrated and gridded. The gridded electric fields $E_g(f)$ from each time series are imaged to produce an images $I_1(f) \dots I_N(f)$. These images are time-averaged to obtain the final image $I(f)$.

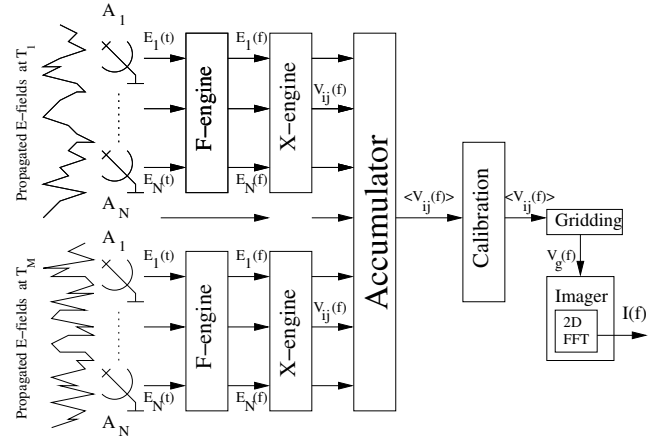

Figure 2. A flowchart of FX imaging in EPIC. The FX process flow shares the F-engine with the MOFF process. Following the F-engine, the electric fields pass through the X-engine to obtain visibilities $V_{ij}(f)$ which are calibrated and time-averaged. Then they are gridded to obtain the gridded visibilities $V_g(f)$ which are then imaged to obtain the image $I(f)$.

3.1 Temporal Fourier transform

This module is common to the MOFF and FX imaging techniques. Time samples of electric fields measured by the antenna and digitized by the A/D converter is Fourier transformed to generate electric field spectra. This step can be parallelized by antennas as shown in Fig. 3. The output is then fed to either MOFF and FX imaging pipelines.

3.2 Antenna-to-Grid Mapping

A grid is generated on the coordinate system in which antenna locations are specified with a grid spacing that is at most $\lambda_{\min}/2$ even at the highest frequency to ensure there is no aliasing even

² EPIC package can be accessed at <https://github.com/nithyanandan/EPIC>

Figure 3. Block diagram of an F-engine. The electric field data streams from antennas are Fourier transformed in parallel to generate electric field spectra.

from regions of the sky far away from the field of view. The number of locations on the grid is restricted to be a power of 2.

The gridding kernel in the simplest case is given by the antenna aperture illumination function, $\tilde{B}(\mathbf{r} - \mathbf{r}_a)$, which can be specified either by a functional form or as a table of values against locations around the antennas. A nearest neighbor mapping from all antenna footprints to grid locations is created using an efficient k-d tree algorithm (Maneewongvatana & Mount 1999). There is no restriction here that the aperture illumination function has to be identical across antennas.

In the most general case, this gridding kernel could contain information on the w -projection effect, and even other time-dependent ionospheric effects. For a stationary antenna array in the absence of any time-dependent effects, this mapping must only be determined once in the antenna array coordinate frame. The antenna-to-grid mapping matrix, $\mathbf{M}(\mathbf{r}, \mathbf{a})$ is described as a transformation matrix from the space of measured electric fields by the antennas (\mathbf{a}) to the antenna array grid denoted by the coordinate \mathbf{r} . Since each antenna occupies a footprint typically the size of its aperture, $\mathbf{M}(\mathbf{r}, \mathbf{a})$, which is generally of size $N_{\text{grid}} \times N_a$, reduces to a sparse block-diagonal matrix with only N_a blocks and roughly N_k non-zero entries per block. This sparse matrix is stored in a Compressed Sparse Row (CSR) format. Fig. 4 illustrates the antenna-to-grid mapping matrix and the grid containing the mapped aperture footprints of the antennas.

3.3 Calibration

Calibration of direct imaging correlators remains an unresolved matter. Contrary to the FX data flow, direct imagers mix the signals from all antennas before averaging and writing to disk. It is therefore essential to apply gain solutions before the gridding step. Previous efforts have resorted to applying FX-generated calibration solutions (Zheng et al. 2014; Foster et al. 2014), or integrating a dedicated FX correlator which periodically forms the full visibility matrix (Wijnholds & van der Veen 2009; de Vos et al. 2009).

In a companion paper to appear soon, we demonstrate a novel calibration technique (EPICal) which leverages the data products formed by direct imaging correlators to estimate antenna complex

Figure 4. Block diagram of an antenna-to-grid mapping. A sparse block-diagonal matrix of total size $N_{\text{grid}} \times N_a$ is created where each block contains roughly the number of pixels covered by the respective kernel. The antenna aperture illumination kernels do not have to be identical to each other. A discrete set of arbitrarily placed antennas are now placed onto a regular grid.

gains. This method correlates the antenna electric field signals with an image pixel from the output of the correlator in the feedback calibration fashion outlined in Morales 2011 (illustrated in Fig. 1 by the arrow leading from the imager to the calibration block). Furthermore it allows for arbitrarily complex sky models, and following the MOFF algorithm places no restriction on array layout, and accounts for non-identical antenna beam patterns. Because only a single correlation is needed for each antenna, the computation complexity scales only as N_{ant} .

The calibration module included in the EPIC repository allows for application of pre-determined calibration solutions, or can solve for the complex gains using the EPICal algorithm.

3.4 Gridding Convolution

The antenna array aperture illumination over the entire grid, $\tilde{\mathbf{W}}(\mathbf{r})$, is obtained by a projection of the individual antenna aperture illuminations:

$$\tilde{\mathbf{W}}(\mathbf{r}) = \sum_a \tilde{\mathbf{W}}_a(\mathbf{r} - \mathbf{r}_a) \quad (15)$$

$$= \mathbf{M}(\mathbf{r}, \mathbf{a}) \mathcal{I}(\mathbf{a}), \quad (16)$$

where, $\mathcal{I}(\mathbf{a})$ is a row of ones. This is achieved by efficient multiplication with the sparse matrix created in the antenna-to-grid mapping process using the sparse matrices module in Python's SciPy package. Unless $\tilde{\mathbf{W}}(\mathbf{r})$ includes time-dependent effects of the ionosphere or the instrument, it needs to be computed just once for the entire observation. However, the gridding of electric fields must be computed at every readout of the electric field spectra,

$$\tilde{\mathbf{E}}(\mathbf{r}) = \mathbf{M}(\mathbf{r}, \mathbf{a}) \tilde{\mathbf{E}}(\mathbf{a}). \quad (17)$$

3.5 Spatial Fourier Transform

Before the spatial Fourier transform, the gridded electric fields are padded with zeros in order to match the grid size and angular size of each image pixel that would have been obtained with software holography of output from an FX correlator.

In MOFF imaging, these are spatially Fourier transformed followed by a squaring operation at every timestamp for every frequency channel. In FX imaging, the spatial Fourier transform is performed only once per integration timescale and does not include a squaring operation.

Figure 5. The auto-correlation of weights of a square shaped antenna aperture in the uv plane (left) and the corresponding directional antenna power response on the sky (right) in coordinates specified by direction cosines. The antenna auto-correlation weights are normalized to a sum of unity yielding a peak response of unity in the antenna’s directional power pattern on the sky. The color scale for the directional power pattern is logarithmic. The black circle indicates the sky horizon and values beyond it are not physical and hence ignored.

3.6 Time-averaging

In MOFF imaging, the measured antenna electric fields and the corresponding holographic electric field images are zero-mean stochastic quantities. Hence, they cannot be time-averaged to reduce noise. The statistical quantity stable with time in this case are the square of the holographic electric field images. Thus, squared images have to be formed at every instant of time before averaging as indicated in equation 14.

In contrast, visibilities measured by an antenna are statistically stable within an integration time interval. Hence, they are averaged after calibration as shown in equation 5. It is advantageous to average them in visibilities before imaging because visibilities represent a compact representation of the information in images. Hence it is more computationally efficient to average antenna pair visibilities rather than images. Since this averaging has been performed already on the visibilities over an integration timescale, the imaging step has to be performed only once per integration cycle. FX imaging holds this advantage as long as the square of the number of antennas is smaller than the number of pixels on the image.

3.7 Dealing with antenna auto-correlations

The squaring operation under MOFF imaging in the image plane introduces antenna auto-correlations around the zero spacing in the uv -plane which are absent in traditional visibility-based imaging. In order for a robust comparison, these auto-correlations have to be removed from both the uv and image planes.

The shape and extent of these auto-correlations can be estimated from the antenna aperture illumination pattern which is a quantity already available from the gridding step. Fig. 5 shows the estimated weights from antenna auto-correlations in the uv -plane (left) and the corresponding response in the image plane (right). The latter is simply the directional antenna power response.

We inverse Fourier transform the squared images and beams back to the uv plane and subtract the estimated auto-correlation kernel scaled to the peak value centered at the zero spacing pixel. The final averaged image is obtained by Fourier transforming the uv plane data and weights with the auto-correlations subtracted to the image plane. These images are now comparable to those obtained from visibility-based imaging. This step of removing auto-

Figure 6. Dirty images (top) and synthesized beams (bottom) obtained from simulated data using antenna-based MOFF algorithm (left) and FX visibility-based software holography (right). The solid black circles in the top panels indicate the simulated source positions. The antenna auto-correlations at zero-spacing have been removed from the MOFF images. The images in either case reconstruct the sources at the right locations with the fluxes expected after multiplication by the antenna power pattern. The synthesized beams from the two algorithms are well matches in size and shape. The overall modulation by the power pattern is seen clearly in both images.

correlations is required to be performed only once per integration timescale and does not add significant cost to the full operation.

4 VERIFICATION

4.1 Simulations

We use the EPIC simulator to generate electric field samples from a sky model. In our simulations, we use 64 frequency channels each of width $\delta f = 40$ kHz, 10 point sources of flux densities 10 Jy at random locations. The number of timestamps integrated in one integration cycle was kept at eight where each A/D timeseries is $1/\delta f = 25 \mu s$ long. We use the MWA array layout (Beardsley et al. 2012) for demonstration. Only the inner 51 tiles within a square bounding box of 150 m on each side were used. We assumed all tiles are identical and have a square shaped electric field illumination footprint 4.4 m on each side.

Fig. 6 shows the dirty images (top) and synthesized beams (bottom) obtained with antenna-based MOFF and FX visibility-based imaging algorithms packaged in EPIC. The antenna auto-correlations that correspond to zero spacing have been removed from the MOFF image and the corresponding synthesized beam. The sky positions of the simulated sources are indicated by solid black circles. The reconstructed sky image has the simulated sources at the expected sky positions in either case. Both algorithms result in images and synthesized beams that are well matched with each other. Their fluxes are modulated by a multiplicative power pattern corresponding to that of a uniform square aperture.

4.2 Differences in outputs

We investigate the two imaging algorithms for differences from the point of view of the quality of their outputs. We begin by comparing the gridded cross-correlation weights in the uv -plane. In MOFF

imaging, weights from antenna auto-correlations have been removed as described in §3.7.

Fig. 7 shows the cross-correlation weights obtained with MOFF imaging (left) and visibility-based imaging (right). The first notable difference is in the weights around zero spacing. Though both show a dominant void around zero-spacing, the void obtained with MOFF algorithm shows many pixels with non-zero weights. In contrast, the zero-spacing void from traditional imaging consists of predominantly zero-valued pixels. The gridding process in the former involves rounding the antenna footprint to the nearest grid pixel. Depending on the exact location of the center of the antenna relative to the grid, the grid pixels that receive contribution from an antenna may be a pixel narrower along one or both axes relative to that from another identical antenna but with a different center location relative to the grid. The resulting auto-correlation footprint will also not necessarily be identical. Hence, using a single expected footprint for subtraction will typically leave some residuals behind as seen in the void region in the weights obtained with MOFF imaging.

These residuals can be mitigated by:

- (i) making the grid spacing finer which makes the rounding error less susceptible to the location of the antenna center relative to the grid, and
- (ii) subtracting each auto-correlation of antenna weights separately by using the shape and extent of the footprint appropriate for that specific antenna aperture.

The latter is the most general solution applicable especially in the case of heterogeneous antenna arrays.

The other notable difference is that weights outside the zero-spacing void in some regions are different from each other at the few percent level though the sum of weights in these regions are identical. For instance, note the difference in weights at $(u, v) \approx (2, -10)$. This is found to arise because with MOFF imaging the antenna locations were rounded to the nearest grid pixel whereas in visibility-based imaging the baseline locations (difference between antenna locations) were rounded to the nearest grid pixel. Since rounding is not a commutative operation (i.e. rounding of the difference value is not necessarily equal to the difference of the rounded values), the gridding operation in the two cases introduces rounding errors in the placement of antenna aperture and cross-correlated aperture weights. Each antenna aperture weight projected to the nearest grid location can be displaced by ~ 1 – 2 pixels. This effect can be mitigated only by making the grid spacing finer.

We study the effect of the differences in gridded weights on the image plane. Fig. 8 shows the difference between the synthesized beams obtained with the two methods. A difference map between the two synthesized beams is shown on top. The amplitude of the difference appears to be modulated by the directional power response of the antenna. At the bottom, in radial bins, the rms of the synthesized beam (gray) and the rms of the difference map (black) are plotted in percentage units relative to the peak (to be read using the axis on the left side of the plot). The antenna power pattern (red; to be read using the scale on the right) is plotted for reference.

The synthesized beam rms is proportional to the antenna power pattern as expected from a point spread function uncorrected for the antenna power pattern. The amplitude of the rms of difference of the synthesized beams is also modulated by the antenna power pattern. The rms of the difference is definitely lesser than the rms of the synthesized beam in the central regions up to $(l^2 + m^2)^{1/2} \lesssim 0.3$. This implies that the beams are well matched in the central regions. In the outer regions, their mismatch is comparable to the rms of

Figure 7. Dirty images (top) and synthesized beams (bottom) obtained from simulated data using antenna-based MOFF algorithm (left) and FX visibility-based software holography (right). The solid black circles in the top panels indicate the simulated source positions. The antenna auto-correlations at zero-spacing have been removed from the MOFF images. The images in either case reconstruct the sources at the right locations with the fluxes expected after multiplication by the antenna power pattern. The synthesized beams from the two algorithms are well matches in size and shape. The overall modulation by the power pattern is seen clearly in both images.

synthesized beams. This indicates the two synthesized beams are not completely randomly different from each other in which case the rms of the difference would have been $\approx \sqrt{2}$ higher than the rms of the each of the synthesized beams. This indicates that while differences exist, large fractions of them are still well matched to each other. Thus the rounding errors in gridding do not affect the statistics of the images or the synthesized beams.

4.3 Application to LWA data

We have analyzed narrow band data from the LWA in New Mexico. This data is in LWA TBN format with 512 voltage time samples from 255 antennas within roughly a diameter of 100 m. The data is centered at a frequency of 74.03 MHz, with a sample rate (equal to the bandwidth) of 100 kHz with 512 complex time samples in a A/D writeout timescale of 5.12 ms, a frequency resolution of 195.3125 Hz and dual polarization. There are 391 such timestamps yielding a total duration of 2 s.

We have matched the cable delays of all the antennas but yet to deploy the calibration pipeline we have developed on this data. Therefore, in subsequent discussion we assumed the data is calibrated.

Fig. 9 shows the image produced with MOFF imaging packaged in EPIC after averaging over the entire 2 s of data and the inner $\approx 80\%$ of bandwidth (roughly 80 kHz). The image is shown in direction cosine coordinates $-l$ along x-axis and m along y-axis. Due to lack of calibration the flux scale is arbitrary. Despite the lack of calibration, only with delay compensation, we see Cyg A and Cas A prominently at $(l, m) \approx (0, 0.125)$, and $(0.4, 0.55)$ respectively and Sgr A faintly at $(-0.5, -0.75)$, thus validating the functionality of the EPIC package.

5 ANALYSIS AND FEASIBILITY

We now investigate the feasibility of implementing the EPIC imager on current and future radio telescopes.

We have profiled the core routines of EPIC line-by-line for

Figure 8. Map of difference between the synthesized beams obtained with the two methods (top) and radial statistics of the synthesized beams and their differences (bottom). The maximum difference is of the order of a few percent. The difference appears to be modulated in amplitude by the power pattern of the antenna.

various ranges of parameters such as antenna filling fraction, maximum baseline length, bandwidth and frequency resolution, integration timescale, etc. for HERA antenna layouts which are highly compact.

Of all steps in the MOFF pipeline that are repeated for every writeout from the F-engine, the slowest step even for dense HERA layouts is found to be the spatial two-dimensional FFT in the imaging stage relative to applying the sparse matrix gridding convolution, squaring or time-averaging. For instance, even in the dense array layout scenario that makes these stages perform the slowest, the gridding convolution, squaring and time-averaging take up only $\approx 40\%$, $\approx 40\%$ and $\approx 15\%$ respectively of the time taken by the spatial Fourier transform. With sparser arrays they will be even faster.

In the visibility-based imaging, the predominant computational

Figure 9. Image from LWA TBN data obtained with MOFF imaging using EPIC package after averaging over 2 s and ≈ 80 kHz. The x- and y-axes denote direction cosines l and m respectively. The antenna voltages are compensated for their respective delays. The flux scale is arbitrary and not calibrated. Cyg A is prominently visible near the center at $(l, m) \approx (0, 0.125)$, Cas A near $(0.4, 0.55)$ and Sgr A near $(-0.5, -0.75)$.

cost is at the X-engine requiring N_a^2 complex multiplications per channel per correlator writeout timescale.

In the following discussions, we will assume that the computational cost for the MOFF imaging is determined by the spatial Fourier transform while that for visibility-based imaging comes from N_a^2 cross-correlations. However, if non-linearities such as non-coplanarity of baselines (Cornwell et al. 2008) and wide-field phenomena like the *pitchfork* effect (Thyagarajan et al. 2015a,b) are to be corrected for, the antenna based illumination footprint can start becoming less compact in the measurement plane and can result in a costlier gridding process.

The number of complex multiplications and additions in the spatial Fourier transform implemented via Fast Fourier Transform (FFT; Cooley & Tukey 1965) is $\approx \beta N_g \log N_g$ where N_g is the number of pixels on the grid and β is a constant that depends on the implementation of twiddle FFT algorithms (Brigham 1974). In our study, we set $\beta = 5$, a value much more conservative than was indicated in Morales (2011). We set the number of complex multiplications in the X-engine in visibility based imaging to N_a^2 .

We consider a variety of current and planned radio telescopes. Their antenna layouts are summarized in Table 1. The size of the layout gives the maximum baseline b_{\max} . The grid spacing is determined by the science goals of the experiment in general. For our purpose, we assume a typical requirement that only the field of view of the antenna is to be imaged. This sets the grid spacing to be equal to the size of the antenna, A_a . Hence, $N_g \approx b_{\max}^2 / A_a$.

Fig. 10 shows the number of complex operations per frequency channel per integration timescale. Telescopes that fall to the left of this line indicate MOFF imaging is computationally more efficient than visibility based imaging. All HERA layouts except possibly HERA-19 are in a parameter space where MOFF imaging holds the

Table 1. Radio telescopes and array layouts.

Telescope (key)	Core size b_{\max} (in m)	Number of Antennas N_a	Antenna size A_a (in m ²)	Frequency f_0 (in MHz)
MWA (MWA-112)	1400	112	16	150
MWA (MWA-496)	1400	496	16	150
LOFAR (LOFAR-C)	3500	24		50
LWA1 (LWA1)	100	256	10	50
LWA-OV ^a (LWA-OV)	200	256	10	50
HERA (HERA-19)	70	19	154	150
HERA (HERA-37)	98	37	154	150
HERA (HERA-331)	294	331	154	150
HERA (HERA-6769)	1330	6769 ^b	154	150
SKA1-Low (SKA1-LC)	1000	750 ^c	962	150
SKA1-Low Dipoles ^d (SKA1-LCD)	1000	192,000 ^c	962	150

advantage. The solid line showing future trajectory of HERA like systems will be clearly favoured by MOFF imaging. The gray shaded area is for a projected LWA expansion and is also predominantly in the region favouring MOFF imaging. It is bounded by the LWA1 and LWA-OV on the left and right respectively. The current (see Table 1) and an expanded layout with a four-fold increase in number of elements over a two-fold increase in b_{\max} provide the bounds at the bottom and top respectively. Current instruments such as MWA and LOFAR lie in parameter space favouring visibility based imaging.

We now consider antenna array layouts described by three quantities essential to radio interferometry, namely, maximum baseline length, number of antennas, and the size of each antenna.

Fig. 11 shows the ratio of the number of computations required with visibility based imaging relative to MOFF imaging and the boundaries where this ratio is unity. The color scale refers to the ratio while using a 1 m antenna element. Pairs of black and white lines of the same line style correspond to a specific antenna size. For a given antenna size (annotated on the plot), the white line denotes the minimum baseline length that could achieve the closest packing

Figure 10. Current and planned instruments in parameter space of number of complex multiplies and adds with MOFF and FX. The dashed line is the boundary at which the number of operations with MOFF and visibility based imaging are equal. MOFF imaging is more efficient for telescopes occupying the left of this line and vice versa. All the HERA layouts except possibly HERA-19 lie in the parameter space favoured by MOFF imaging. And so are SKA1-LC and SKA1-LCD. The solid black curve shows the projected trajectory of bigger close-packed hexagonal layouts similar to HERA. The gray shaded area denotes the projected trajectory of the LWA bounded by LWA1 (left edge), LWA-OV (right edge), current layout (bottom) and a four-fold increase in the number of elements in a two-fold increase in the core size (top). Current instruments such as MWA and LOFAR fall in a region favoured by visibility based imaging.

as a function of the number of antennas. Regions to the right of the white line for a given antenna size imply a physically impossible scenario where antennas will have to be packed overlapping with each other. For the same antenna size, the black line denotes the boundary where the ratio of the number of computations with either algorithm becomes unity. Regions to the right of the black lines favour usage of the MOFF algorithm. Thus the wedge between the white and black lines denotes the region in parameter space where MOFF algorithm holds a definite advantage while visibility based algorithms will be favoured to the left of the black lines. As antenna size increases the maximum number of antennas for a dense packing as a function of baseline length decreases. Hence the white lines shift leftward as antenna size increases. Similarly, with increase in antenna size, N_g also decreases when field of view imaging is achieved with an increasing grid spacing equal to antenna size and hence lowers the amount of computations required with the MOFF algorithm. This shifts the black curves leftward. HERA-331, HERA-1027, LWA1, SKA1-LC and SKA1-LCD are inside their respective wedges indicating they are in regions that favour the usage of MOFF imaging. For fixed baseline length, regions favouring the MOFF algorithm tend to be towards large N_a indicating large-N dense array layouts with smaller antenna elements are best suited for deploying the MOFF algorithm.

6 CONCLUSIONS

As radio astronomy is entering a new era, advances in instrumentation have to be accompanied by equal advances in processing techniques to manage computational resources. Many future radio telescopes such as the SKA, HERA and LWA are headed towards

Figure 11. Current and instruments planned for future in parameter space of baseline length and number of antennas with MOFF and FX. Color scale shown is for the ratio of number of computations required by visibility based imaging to that by the MOFF algorithm. Different line styles denote different antenna sizes annotated. For a given antenna size, the corresponding white line denotes the maximum number of antennas that can be packed inside various baseline lengths. The region to the right of the white lines for corresponding antenna size is physically disallowed. Regions to the left of the black lines of the same corresponding antenna size (or line style) favours usage of visibility based imaging. Region inside the wedge enclosed by the black and white lines favours using the MOFF algorithm for any given antenna size. These wedges shift leftward with increasing antenna size. HERA-331, HERA-1027, LWA1, SKA1-LC and SKA1-LCD are inside their corresponding wedges that favour the usage of MOFF imaging.

the large-N dense array layout model for which computational cost from traditional FX/XF correlator based architecture and visibility based imaging starts rising steeply. We have provided the first software demonstration of a general purpose imaging algorithm using our generic and efficient EPIC software that is designed to bring this cost down from $O(N^2)$ to $O(N \log N)$. Under the class of direct imaging techniques, ours is one of the most generic – neither does it place any constraint on the array layout to be on a regular grid nor does it require the antenna array to be homogeneous.

Our package, now publicly available, written in object oriented Python is highly modularized and parallelizable. It includes an implementation of the MOFF algorithm in addition to visibility based software holography imaging and a data simulator for sky models. It has been successfully tested on simulated as well as real LWA observations.

The MOFF algorithm packaged with EPIC is already found to be most suitable for many present and planned radio telescopes such as the LWA, HERA and SKA. In general, MOFF is most suited to operate in the region of parameter space characterized by dense packing of a large number of antennas especially when consisting of a large number of small antenna elements.

A unique and significant advantage is the instantaneous availability of calibrated time-domain images bundled together with the hardware frontend such as the F-engine as an integrated module. Hence, it is a compelling candidate for time-domain radio astronomy, e.g. search for and monitoring of transients. Transient detection pipeline at the backend of EPIC can be fine-tuned to target fast transients such as the Fast Radio Bursts (FRB; Thornton et al. 2013) on

millisecond timescales at GHz frequencies or slow transients from planetary and exoplanetary origins at frequencies around 100 MHz.

Thus, EPIC with the MOFF algorithm packaged is uniquely poised to offer a substantial advantage to imaging with large-N dense arrays typical of next-generation radio telescopes as well as push the frontiers of time-domain astronomy to fill gaps in understanding the science behind phenomena responsible for extreme transient events in the Universe.

In the near future, we plan to upgrade our current Python implementation of EPIC to a GPU based pipeline in order to operate on real-time data and develop a transient trigger and monitor backend. In the meanwhile, we plan to demonstrate the capability of EPIC to calibrate and image from heterogeneous arrays and incorporate corrections for non-coplanarity of baselines and direction-dependence of calibration.

ACKNOWLEDGEMENTS

We thank Larry D’Addario, Gregg Hallinan and Harish Vedantham for their valuable inputs.
